Adaptive Estimation of the State of Charge for Lithium-Ion Batteries: Nonlinear Geometric Observer Approach

Wang, Y.; Fang, H.; Sahinoglu, Z.; Wada, T.; Hara, S.

TR2014-094 September 2014

Abstract

This paper considers the state of charge (SoC) and parameter estimation of lithium-ion batteries. Different from various prior arts, where estimation is based on local linearization of a nonlinear battery model, nonlinear geometric observer approach is followed to design adaptive observers for the SoC and parameter estimation based on nonlinear battery models. A major advantage of the proposed approach is the possibility to establish the exponential stability of the resultant error dynamics of state and parameter estimation. The proposed adaptive observers are shown to be robust with respect to unmodeled process uncertainties. Analysis also shows the design tradeoff between the convergence rate and the robustness of the estimation error dynamics with respect to the measurement noise. Simulation and experimental results validate the effectiveness and main advantages of the proposed approach. Error analysis is presented and explains the experimental results.

IEEE Transactions on Control Systems Technology
Adaptive estimation of the state of charge for Lithium-ion batteries: Nonlinear geometric observer approach

Abstract—This paper considers the State of Charge (SoC) and parameter estimation of Lithium-ion batteries. Different from various prior art, where estimation is based on local linearization of a nonlinear battery model, nonlinear geometric observer approach is followed to design adaptive observers for the SoC and parameter estimation based on nonlinear battery models. A major advantage of the proposed approach is the possibility to establish the exponential stability of the resultant error dynamics of state and parameter estimation. The proposed adaptive observers are shown to be robust with respect to unmodeled process uncertainties. Analysis also shows the design tradeoff between the convergence rate and the robustness of the estimation error dynamics with respect to the measurement noise. Simulation and experimental results validate the effectiveness and main advantages of the proposed approach. Error analysis is presented and explains the experimental results.

Index Terms—State of charge, batteries, adaptive estimation, geometric method, nonlinear systems.

I. INTRODUCTION

LITHIUM-ION (Li+) batteries have been widely used in numerous applications including consumer electronics, automotive, and power tools, due to the high capacity but reduced size, superior power performance, and long cycle life [1]. Nowadays battery management systems (BMSs) are used to monitor the battery status and regulate the charging and discharging processes for real-time battery protection and performance improvement [2], [3]. An accurate state of charge (SoC) of the battery, usually defined as the percentage ratio of the present battery capacity to the maximum capacity, is a prerequisite to have a desirable BMS.

The SoC of a battery is difficult to measure, and its accurate estimation is known as a challenging task. Two straightforward SoC estimation methods are voltage translation and Coulomb counting [3]. Both methods have limitations such as the former requires the battery to rest for a long period and cut off from the external circuit to measure the Open Circuit Voltage (OCV), and the latter suffers cumulative integration errors and noise corruption.

Recently model-based approaches have attracted a lot of attention to improve the SoC estimation accuracy. For instance, equivalent circuit models (ECMs) and extended Kalman filter (EKF) type of approaches have been used extensively to estimate the SoC with approximate dynamic error bounds [4]–[6]. Nonlinear observer design approaches have also been applied to construct ECM-based nonlinear SoC estimators, e.g. sliding mode observer [7], adaptive model reference observer [8], Lyapunov-based observer [9] etc. ECM-based approaches have the benefit of simplicity and low computation but sacrifice physical meaning of model parameters thus may limit their uses for battery monitoring.

Electrochemical or physics-based models, for instance the pseudo two dimensional model [10], [11] and single particle models [12], [13], are derived from electrochemical principles which describe intercalation and diffusion of lithium ions and conservation of charge within a battery. Electrochemical models have the merit of ensuring each model parameter to retain a proper physical meaning; on the other hand, they take the form of nonlinear partial differential equations (PDEs) thus often necessitates model simplification or reduction for control and estimation purposes. A linear reduced-order electrochemical model is established in [14], to which the classical KF is employed for the SoC estimation. In [15], the EKF is implemented to estimate the SoC via a nonlinear ordinary differential equation (ODE) model obtained from PDEs by finite-difference discretization. The unscented Kalman filter (UKF) is used in [16] to avoid model linearization for more accurate SoC estimation. Rather than using the ODE model, nonlinear SoC estimators are also developed in [17], [18] through direct manipulation of PDEs.

Adaptive SoC estimation, which enables the SoC estimation with unknown model parameters, has been discussed for some ECMs and electrochemical models, e.g., [6], [19]–[22]. This paper is an extension of the work [22] by including alternative adaptive observer design, robustness and applicability analysis of the proposed adaptive observers, and experimental study. This paper makes new contributions to study of this topic by proposing nonlinear geometric observer approach.
for adaptive SoC estimation. The proposed nonlinear adaptive SoC estimators admit straightforward analysis of the resultant error dynamics. Specifically, for the case where no mismatch between the battery model and the physical process is present, the error dynamics are exponentially stable; with bounded model uncertainties, the error dynamics are input-to-state stable. Extensive analysis, and simulation and experimental results are provided to validate the methodology.

The rest of this paper is organized as follows. Section II introduces the working mechanism of Li⁺ batteries and simplified battery models. Section III presents adaptive observers for the SoC and parameter estimation, and robustness analysis. Simulation and experiment results are provided in Section IV to verify the proposed design approach. The paper is concluded by Section V.

II. SIMPLIFIED BATTERY MODELS

This section includes a brief introduction of the working mechanism of Li⁺ batteries, the single particle model (SPM) [2], and simplified models to which nonlinear geometric observer approach can be applied for the SoC estimation.

A. The Working Mechanism of Li⁺ Batteries

A schematic visualization of a Li⁺ battery is presented in Fig 1(a). The positive electrode is typically made from Li compounds, e.g., Li₄Mn₂O₄ and Li₄CoO₂. Small solid particles of the compounds are compressed to form a porous structure. Similarly, the negative electrode, usually containing graphite particles, is also porous. The interstitial pores at both electrodes provide intercalation space, where the Li⁺ can be moved in and out and stored. The electrolyte contains free ions and is electrically conductive, where the Li⁺ can be transported. The separator separates the electrodes apart. It allows the exchange of Li⁺ from one side to the other, but prevents electrons from passing through. Electrons are thus forced to flow through the external circuit.

When the battery is being charged, Li⁺ are extracted from particles at the positive electrode into the electrolyte, driven by reaction at the particle/electrolyte interface, and particles at the negative electrode absorbs Li⁺ from the electrolyte. This process not only generates an influx of Li⁺ within the battery, but also builds up a potential difference between the positive and negative electrodes. When it is reversed, the battery is discharging. The chemical reactions in the positive and negative electrodes are, respectively, described by

\[
\text{Li}_q\text{Mn}_2\text{O}_4 \xrightarrow{\text{charge}} \text{Li}_{q-l}\text{Mn}_2\text{O}_4 + l\text{Li}^+ + le^- \\
q\text{Li}^+ + qe^- + C \xrightarrow{\text{discharge}} \text{Li}_qC
\]

A rechargeable battery has various features including rate capacity effect (RCE), recovery effect (RE), and hysteresis effect (HE). A battery model capturing all these effects is important for accurate SoC and state of health estimation. It is however difficult to find practical models that interpret the RCE and the RE using electrochemical states [23]. A commonly used model for characterizing the electrochemical mechanism of a Li⁺ battery is presented in [10]. The model includes four quantities solid and electrolyte Li⁺ concentration and potential as state variables, whose dynamics, e.g. material balance and charge balance, are captured by PDEs [13]. In addition, these state variables are coupled by a charge-transfer kinetic resistance at the particle surface which is given by the Butler-Volmer equations. Interested readers are referred to [2], [10], [13] for details.

B. The Single Particle Model

The single particle model (SPM) simplifies each electrode as a spherical particle with area equivalent to the active area of the electrode [24], [25]. The dynamics of electrolyte concentration and potential are ignored. Although unable to capture all electrochemical processes in batteries, the SPM reduces complexities in identification, estimation and control design to a large extent [15], [18]. To proceed further, a review of the SPM is provided, with the nomenclature shown in Table I.

Input and output of the battery: The external input to the battery is the current \( I(t) \) with \( I(t) < 0 \) for charge and \( I(t) > 0 \) for discharge. The measured output of the battery is the terminal voltage, which is the potential difference between the two electrodes, and given by

\[
V(t) = \Phi_{x,p}(t) - \Phi_{x,n}(t).
\]  

Conservation of Li⁺ in the electrode phase: The migration of Li⁺ inside a particle is caused by the gradient-induced diffusion. Its dynamics can be modeled from the Fick’s second law and given by

\[
\frac{\partial c_{x,j}(r,t)}{\partial t} = \frac{1}{r^2} \frac{\partial}{\partial r} \left( D_{x,j} r^2 \frac{\partial c_{x,j}(r,t)}{\partial r} \right),
\]
with the following initial and boundary conditions
\[ c_{s,j}(r,0) = c_{s,j}^0, \quad \frac{\partial c_{s,j}}{\partial r} \bigg|_{r=0} = 0, \quad \frac{\partial c_{s,j}}{\partial r} \bigg|_{r=\bar{r}} = -\frac{1}{D_{s,j}} J_j. \]

It is noted that \( J_j \) is the molar flux at the electrode/electrolyte interface of a single particle. When \( j = n \) and \( p \), respectively,
\[ J_n(t) = \frac{I(t)}{F S_n}, \quad J_p(t) = -\frac{I(t)}{F S_p}. \]

Electrochemical kinetics: The molar flux \( J_j \) is governed by the Butler-Volmer equation:
\[ J_j(t) = \frac{J_{n,j}}{F} \left[ \exp \left( \frac{\alpha_a F}{R T} \eta_j(t) \right) - \exp \left( \frac{\alpha_c F}{R T} \eta_j(t) \right) \right], \quad (3) \]
where \( \eta_j(t) = \Phi_{s,j}(t) - \Phi_{e,j}(t) - U(c_{s,j}(t)) - F R_{e,j} J_j(t) \). The electrolyte phase can be represented by a resistor \( R_{e,j} \) in the SPM, implying \( \Phi_{e,j} \) can be expressed as \( \Phi_{e,j}(t) = R_{e,j} I(t) \). Hence, \( \eta_j \) becomes
\[ \eta_j(t) = \Phi_{s,j}(t) - U(c_{s,j}(t)) - F \bar{R}_j J_j(t), \quad (4) \]
where \( \bar{R}_j = S_j R_{e,j} + R_{f,j} \).

The SPM is represented by \( (1)-(3) \), in which \( I \) is the external input, \( c_{s,j} \) and \( \Phi_{s,j} \) are the variables showing the battery status, and \( V \) is the model output. The SPM could not fully capture the RCE since assumptions used in its derivation are merely valid at low charge-discharge rates.

### C. A Simplified Battery Model

Nonlinear geometric observer approach assumes a system represented by ODEs, thus the SPM should be further simplified. Many techniques have been proposed to meet this purpose. One way is to introduce a volume average concentration as a state variable thus eliminate the two diffusion PDEs of \( \mathrm{Li}^+ \) concentration in particles.

**Average \( \mathrm{Li}^+ \) concentration in the electrode phase:** Throughout the paper the average concentration of \( \mathrm{Li}^+ \) in the particle is treated as the measure of the battery capacity, or equivalently, the SoC. For an electrode particle, it is defined as
\[ c_{s,j}^{\text{avg}}(t) = \frac{1}{\Omega} \int c_{s,j}(r,t) d\Omega, \quad (5) \]
where \( \Omega \) denotes the volume of the particle sphere. From \( (2) \), it is obtained that
\[ c_{s,j}^{\text{avg}}(t) = \frac{1}{\Omega} \int \frac{\partial c_{s,j}(r,t)}{\partial t} d\Omega \]
\[ = \frac{1}{\Omega} \int \frac{1}{\Omega} \frac{\partial}{\partial r} \left( D_{s,j} r^2 \frac{\partial c_{s,j}(r,t)}{\partial r} \right) d\Omega \]
\[ = \varepsilon_j D_{s,j} \frac{\partial c_{s,j}(r,t)}{\partial r} \bigg|_{r=\bar{r}_j}, \quad (6) \]
where \( \varepsilon_j \) is a constant coefficient. Depending on the electrode polarity, \( (6) \) splits into
\[ c_{s,n,p}^{\text{avg}}(t) = -\varepsilon_{n,p} I(t), \quad (7) \]
\[ c_{s,n,p}^{\text{avg}}(t) = \varepsilon_{n,p} I(t). \quad (8) \]

It is noted from \( (7)-(8) \) that \( c_{s,j}^{\text{avg}} \) is linearly proportional to the input current \( I \). In other words, \( c_{s,j}^{\text{avg}} \) is equal to the initial value \( c_{s,j}^{\text{avg}}(0) \) plus integration of \( I \) over time. This illustrates that the change of SoC depends linearly on \( I \) as a result of \( c_{s,j}^{\text{avg}} \) indicating SoC. Such a relationship has not only been presented for electrochemical models, e.g., [14], but has also been justified in ECMs, e.g., [5], [26] and the references therein.

**Terminal voltage:** Suppose there exists a function \( \varphi \) such that \( c_{s,j}(t) = \varphi(c_{s,j}^{\text{avg}}(t)) \) and define \( \bar{U} = U \circ \varphi \), where \( \circ \) denotes composition of two functions. Using \( (4) \), \( (1) \) becomes
\[ V(t) = \bar{U}(c_{s,n,p}^{\text{avg}}(t)) - \bar{U}(c_{s,n,p}^{\text{avg}}(t)) + \eta_n(t) + (\bar{R}_p - \bar{R}_n)I(t). \]
With \( \alpha_a = \alpha_c = 0.5 \), it follows from \( (3) \) that
\[ \eta_n(t) = 2R T \sinh^{-1} \left( \frac{J_n(t) F}{2J_{0,n}} \right) \]
\[ = 2R T \sinh^{-1} \left( \frac{\varepsilon_n I(t)}{2J_{0,n}} \right), \]
\[ \eta_p(t) = 2R T \sinh^{-1} \left( \frac{J_p(t) F}{2J_{0,p}} \right) \]
\[ = 2R T \sinh^{-1} \left( \frac{\varepsilon_p I(t)}{2J_{0,p}} \right). \]
Thus \( V(t) \) becomes
\[ V(t) = \bar{U}(c_{s,n,p}^{\text{avg}}) - \bar{U}(c_{s,n,p}^{\text{avg}}) \]
\[ + \left[ \frac{2R T}{F} \left( \sinh^{-1} \left( \frac{\varepsilon_n I(t)}{2J_{0,n}} \right) - \sinh^{-1} \left( \frac{\varepsilon_n I(t)}{2J_{0,n}} \right) \right) \right] \]
\[ + (\bar{R}_p - \bar{R}_n)I(t). \quad (9) \]
As such, $V(t)$ consists of two parts. The first is the open-circuit voltage (OCV) that relies on $\bar{U}(U_{ss}, I)$, and the second is the direct feedthrough from $I$ to $V$.

System (7)-(9) provides a concise characterization of the battery dynamics. As pointed out in [18], the SPM implies the conservation of Lithium ions within two particles, or equivalently, that $c_{SS,\beta}(t)$ can be represented as a linear function of $c_{SS,\beta}(t)$. This fact allows the reduction of (7)-(8) into one differential equation. With $\bar{c}_{SS,\beta}(t)$ as the independent variable, the battery dynamics is captured by (7) and (9). As aforementioned, $\bar{c}_{SS,\beta}(t)$ is arguably equivalent to the SoC. Denoting the SoC by a state $x \in [0, 1]$, and defining the input $u$ and the output $y$ of the model as the charge current $I$ and the terminal voltage $V$ of the battery, respectively, we have the battery model as follows

$$\dot{x} = -\alpha u,$$
$$y = h(x, \beta) + g(u, \gamma), \quad (10)$$

where $\alpha, \beta = (\beta_1, \beta_2, \beta_3)$, and $\gamma = (\gamma_0, \gamma_1, \gamma_2, \gamma_3)$ are unknown parameters, $h(x, \beta)$, the part containing $U$ in (9), takes the parametric form of $h(x) = \beta_1 \ln(x + \beta_2) + \beta_3$, and $g(u, \gamma)$ corresponding to the part involving $I$ in (9) is expressed as $g(u, \gamma) = \gamma_0 \sinh^{-1}(\gamma u) - \sinh^{-1}(\gamma u) + \gamma u$, where $\gamma$ for $i = 0, 1, 2, 3$ are from (9).

Due to the negligence of diffusion in solid particles, the battery model (10) have limited capability to represent the RCE, the RE and the HE. This paper however uses the battery model (10) mainly for illustration purpose, i.e., to demonstrate how nonlinear geometric observer approach can be followed to perform adaptive SoC estimation.

**Remark 2.1:** The thermodynamics of batteries are not covered by the SPM and the simplified model (10). Ignoring thermodynamics however might not impose significant restriction to the applicability of the proposed approach. Loosely speaking, the effect of thermodynamics on both models can be compensated by making parameters time-varying. Adaptive state estimation based on (10) is possible for cases where parameters are either constant or time-varying but with bounded time derivative [27]. If the thermodynamics evolves in a much slower time scale than the estimation error dynamics, the adaptive estimator generally can track the resultant slow time-varying parameters and original system state with reasonable accuracy.

### D. A Switched Battery Model

An intuitive generalization of the model (10) can be done by addressing the HE in the OCV-SoC relationship, which is characterized by $h(x, \beta)$. We consider the following switched battery model

$$\dot{x} = -\alpha u,$$
$$y = \begin{cases} h(x, \beta) + g(u, \gamma), & u > 0, \\ h(x, \bar{\beta}) + g(u, \gamma), & u \leq 0, \end{cases} \quad (11)$$

where $\bar{\beta} = (\bar{\beta}_1, \bar{\beta}_2, \bar{\beta}_3)$ is constant. Here $h(x, \beta)$ and $h(x, \bar{\beta})$ parameterize the discharge and charge OCV-SoC curves, respectively. As will be shown later, nonlinear geometric observer approach can also be applied to the switched model (11) for adaptive SoC estimation. The resultant SoC estimation is more accurate than that based on the model (10).

### III. Main Results

Similar to [21], a two-stage approach is used to perform adaptive SoC estimation:

- **Stage 1:** As $h(\cdot)$ represents the OCV, it is determined using the SoC-OCV data set to identify parameters $\beta$ for the battery model (10), or to identify parameters $\beta$ and $\bar{\beta}$ for the battery model (11).
- **Stage 2:** After $\beta$ and/or $\bar{\beta}$ is identified, the state $x$ and parameters $\alpha, \gamma$ are estimated simultaneously by nonlinear geometric observer approach.

The identification in Stage 1 has been well-studied in literatures. As an example, one can formulate it as a nonlinear least squares data fitting problem and solve the resultant nonlinear programming problem. Interested readers are referred to [28], [29] for further details. This paper focuses on the problem in Stage 2, where parameters $\beta$ are treated as known constants, and the state and parameter estimation is performed using nonlinear geometric observer approach.

We first define a local adaptive observer for a general system

$$\dot{\hat{\xi}} = f(\xi, \Theta),$$
$$y = h(\xi), \quad (12)$$

where $\xi \in \mathbb{R}^n$ is the system state, $f : \mathbb{R}^n \times \mathbb{R}^m \to \mathbb{R}^n$ is a smooth vector field, $\Theta \in \mathbb{R}^m$ is the unknown parameter vector, and $h : \mathbb{R}^n \to \mathbb{R}^p$ is a vector of smooth functions. Here the notation $h$ is abused, which should not incur any confusion given the context.

**Definition 3.1:** [30] A local adaptive observer for system (12) with the presence of the unknown parameter $\Theta$ in $f$ is a finite dimensional system

$$\dot{w} = \alpha_1(w, \hat{\Theta}, y(t)), \quad w \in \mathbb{R}^r, \quad r \geq n,$$
$$\dot{\hat{\Theta}} = \alpha_2(w, \hat{\Theta}, y(t)), \quad \hat{\Theta} \in \mathbb{R}^m,$$
$$\dot{\hat{\xi}} = \alpha_3(w, \hat{\Theta}, y(t)), \quad \hat{\xi} \in \mathbb{R}^n$$

driven by $y(t)$, such that for every $\hat{\xi}(0) \in \mathbb{R}^n, w(0) \in U_w \subset \mathbb{R}^r, \hat{\Theta}(0) \in U_\Theta \subset \mathbb{R}^m$, where $U_w, U_\Theta$ are the neighborhoods of $\xi(0), \Theta$, respectively, for any value of the unknown parameter $\Theta$ and for any bounded $\|\hat{\xi}(t)\|, \forall r \geq 0$,

1. $\|w(t)\|, \|\hat{\Theta}(t)\|$ and $\|\xi(t) - \hat{\xi}(t)\|$ are bounded, $\forall r \geq 0$.
2. $\lim_{t \to \infty} \|\xi(t) - \hat{\xi}(t)\| = 0$.

In Definition 3.1, a local adaptive observer is defined for a system where the output function $h$ does not have explicit dependence on unknown parameters. This is without loss of generality because one can introduce a parameter dependent state transformation to put a general system into the form (12).

### A. Nonlinear Geometric Observer Approach

We first define some notation. Given a $C^m$ vector field $f : \mathbb{R}^n \to \mathbb{R}^n$, and a $C^m$ function $h : \mathbb{R}^n \to \mathbb{R}$, the function $L_f h(x) = \frac{\partial h(x)}{\partial x} f$ is the Lie derivative of $h(x)$ along $f$. Repeated Lie
derivatives are defined as \( L^k_f h(x) = L_f(L^k_f h(x)) \), \( k \geq 1 \) with \( L^0_f h(x) = h(x) \).

Nonlinear geometric observer approach generally requires a system in some forms which enable the simplification of observer design and establishment of the error dynamics stability. Typically, the first step for nonlinear geometric observer approach is to put the original system into an observable form by change of coordinates. As a next step starting from the observable form, various techniques, for instance output transformation [31], [32], state transformation [31], [33], time scale transformation [34]–[36], dynamics extension [37], and approximate transformation [38], can be considered to further simplify the system dynamics. The transformed system typical takes a certain special structure, e.g., observer form [31], [33], [39], block triangular forms [40]–[43], time scaled observer forms [34], [36], [44], and adaptive observer forms [45]–[47] etc. As the final step, observer design for a system admitting special coordinates can be readily performed, and usually have properties: reduced design complexity, straightforward determination of the observer gain, and simulated estimation error dynamics. Although nonlinear geometric observer approach allows systematic and simple observer designs, and yields stable estimation error dynamics, it suffers from limited range of applicability.

For a locally uniquely observable single input single output (SISO) system,
\[
\begin{align*}
\hat{\xi} &= f(\xi) + g(\xi) u, \\
y &= h(\xi),
\end{align*}
\]
where \( u \in \mathbb{R} \) and \( h : \mathbb{R}^n \rightarrow \mathbb{R} \), the observable form exists and is uniquely defined as follows [48]
\[
\dot{x} = \begin{bmatrix} x_2 \\ \vdots \\ L_n^p \Phi (h(\xi)) \end{bmatrix} + \begin{bmatrix} g_1 (x_1) \\ \vdots \\ g_n (x) \end{bmatrix} u, \tag{13}
\]
where \( x = \Phi (\xi) = (h(\xi), \ldots, L_n^p h(\xi))^T \) and \( \xi = \Phi^{-1}(x) \). Observability ensures that \( x \) defines new coordinates. For a multi-output system, the observable form is not uniquely defined due to the non-uniqueness of the observability definitions and observability indices [40], [42]. Readers are referred to [30], [40], [42], [48], [49] for details about observability and observable forms. One can readily verify that the battery model (10), SISO with one state, is locally observable. The identifiability of parameters can be verified by performing observability analysis on the augmented system which includes (10) and the following dynamics
\[
\begin{align*}
\alpha &= 0, \\
\hat{y}_1 &= 0.
\end{align*}
\]
Readers are referred to [50] for detailed observability and identifiability analysis.

Earlier work on adaptive observer with nonlinear parameterizations includes a local adaptive observer [51] based on a nonlinearly parameterized observer form, and a semi-global adaptive observer [47] etc. The battery model (10) does not admit the nonlinearly parameterized observer form in [51]. This paper mainly performs adaptive Soc estimation based on work [47]. The fact that this paper applies results of work [47] however shall not prevent one from applying other relevant works. For an SISO system, work [47] considered adaptive observer design for a class of nonlinearly parameterized system on the basis of the following form
\[
\begin{align*}
\dot{z} &= Az + \varphi (z, u, \Theta), \\
y &= Cz,
\end{align*}
\]
where \((A, C)\) is in Brunovsky observer form, \( z = (z_1, \ldots, z_n)^T \in \mathbb{R}^n \) is the state vector, \( \Theta \in \mathbb{R}^m \) is the unknown parameter vector, \( u \in \mathbb{R}^3 \) is the input vector, and \( \varphi (z, u, \Theta) \) takes the following form
\[
\varphi (z, u, \Theta) = \begin{bmatrix} \varphi_1 (z_1, u, \Theta) \\ \vdots \\ \varphi_n (z_n, u, \Theta) \end{bmatrix}.
\]
Note that \( \varphi (z, u, \Theta) \) has triangular dependence on \( z \) to enable high gain observer design [48], [52].

Given a nonlinear system in the form (14), work [47] proposed the following dynamical system
\[
\begin{align*}
\dot{z} &= A\hat{z} + \hat{\varphi} - \Delta_\theta \Delta_\theta^T (S^{-1} + \gamma_1 T^{-1}T^T) C^T K (y - \hat{y}), \\
\dot{\hat{\Theta}} &= \Theta P^T C^T \gamma_2 T P^T \Theta, \\
\dot{\gamma}_2 &= -\Theta P^T C^T \gamma_1 T P^T \Theta, \\
P_0 &= P_0 > 0,
\end{align*}
\]
where \( \vartheta \) is a positive constant, \( \dot{\varphi} = \varphi (\hat{z}, u, \hat{\Theta}) \), \( \hat{y} = C\hat{z} \), \( \Delta_\theta = \text{diag} (1, \frac{1}{\tau_1}, \ldots, \frac{1}{\tau_m}) \), and \( S \) is the unique solution of the algebraic Lyapunov equation
\[
S + A^T S + SA - C^T C = 0.
\]
To show the system (15) is a semi-global adaptive observer of the original system (14), the following technical assumptions are assumed.

**Assumption 3.2:** [47, Assum. (A1)] The state \( z(t) \), the control \( u(t) \) and the unknown parameters \( \Theta \) are bounded, i.e., \( z(t) \in Z, u(t) \in U \) for \( t \geq 0 \) and \( \Theta \in \Omega \) where \( Z \subset \mathbb{R}^n, U \subset \mathbb{R}^m \) and \( \Omega \subset \mathbb{R}^m \).

**Assumption 3.3:** [47, Assum. (A2')] The function \( \varphi (z, u, \Theta) \) is Lipschitz with respect to \( z, \Theta \) uniformly in \( u \) where \( (z, u, \Theta) \in Z \times U \times \Omega \).

**Assumption 3.4:** [47, Assum. (A3')] The nonlinear parametrization function \( \varphi (z, u, \cdot) \) is one to one from \( \mathbb{R}^m \) into \( \mathbb{R}^m \).

**Assumption 3.5:** [47, Assum. (A4')] The inputs \( u \) are such that for any trajectory of system (15) starting from \( (z(0), \Theta(0)) \in Z \times \Omega \), the matrix \( CT \) is persistently exciting, i.e., \( \exists \delta_1, \delta_2 > 0; \exists T > 0; \forall t > 0 \)
\[
\delta_1 I_n \leq \int_t^{t+T} \gamma_2 T^T C T \gamma_1 T P^T \Theta \leq \delta_2 I_n,
\]
where \( I_n \in \mathbb{R}^{n \times n} \) is the identity matrix.

[47, Thm. 4.2] established that the system (15) is a semi-global adaptive observer of the original system (14). For completeness of this paper, we recite the theorem as follows.
Theorem 3.6: [47, Thm. 4.2] under assumptions (A1),(A2’),(A3’) and (A4’), system (15) is an adaptive observer for system (14) with an exponentially error convergence for relatively high values of $\theta$.

B. System Transformation

Following the nonlinear geometric observer approach in Section III-A, we first transform the battery model (10) into certain forms which facilitate adaptive observer design. To simplify the presentation, this paper assumes $g(u, \gamma)$ in system (10) has a linear parametrization. Specifically, consider the following battery model

$$\begin{align*}
\dot{x} &= \alpha u, \\
y &= \beta_1 \log(x + \beta_2) + \beta_3 + \gamma u,
\end{align*}$$

where $x$ is the SoC of a battery, $\beta_i$ are known parameters, and $\gamma, \alpha$ are unknown parameters.

Remark 3.7: Assuming $g(u, \gamma) = \gamma_1 u$ is mainly to simplify the state transformation and the expression of the resultant transformed system, and without loss of generality. With the original $g(u, \gamma)$, the state transformation is taken as follows

$$\xi(x, u, \gamma) = \beta_1 \log(x + \beta_2) + \beta_3 + g(u, \gamma),$$

which is a diffeomorphism over $\mathbb{R}^+$. The inverse state transformation can be similarly computed as follows

$$x + \beta_2 = \exp\left(\frac{y - \beta_3 - g(u, \gamma)}{\beta_1}\right).$$

The procedure followed in the sequel to develop adaptive observers is therefore still applicable for the original $g(u, \gamma)$ case. Simplifying $g(u, \gamma)$ as $\gamma_1 u$ can also be justified by its practical usefulness. That is: because $\gamma_2, \gamma_3$ are usually small positive constants, the ignored term $\gamma_1 (\text{asinh}(\gamma_1 u) - \text{asinh}(\gamma_1 u))$ can be approximated by a linear function of $u$, thus can be lumped into the term $\gamma_1 u$. For a particular battery tested in the experiment, $\gamma_1$ is in the order of millihms (m-Ohm). We therefore take $\gamma_2$ and $\gamma_3$ at the same order, i.e., $\gamma_2 = 1e-3, \gamma_3 = 2e-3$, and examine the plot of the ignored term versus $u$. As shown in Figure 2, the ignored term is almost linear in $u$ over a wide range of input current: from -50Amps to 50Amps. Note that the tested battery has a nominal capacity 5Amp-hours (Ah) and the 50Amps current is quite large (10C). A less rigorous interpretation of the aforementioned analysis is that parameters $\gamma_i, 0 \leq i \leq 3$ are closely coupled and almost indistinguishable, and can be lumped into one parameter.

Putting (16) into observable form (13) with unknown parameterizations requires the following parameter dependent state transformation

$$\begin{align*}
\xi(x, u, \gamma_1) &= \beta_1 \log(x + \beta_2) + \beta_3 + \gamma_1 u, \\
\dot{\xi} &= \beta_1 \frac{\alpha}{x + \beta_2} u + \gamma_1 \dot{u},
\end{align*}$$

where $\xi$ is the new state variable and denotes the terminal voltage of the battery. We have

$$\begin{align*}
x + \beta_2 &= \exp\left(\frac{y - \beta_3 - \gamma_1 u}{\beta_1}\right),
\end{align*}$$

where $x + \beta_2$ can be solved as

$$\begin{align*}
\dot{\xi} &= \beta_1 \frac{\alpha}{x + \beta_2} u + \gamma_1 \dot{u},
\end{align*}$$

We rearrange the transformed system and have

$$\begin{align*}
\dot{\xi} &= \phi(y, u, \gamma, \alpha) + \gamma_1 \dot{u}, \\
y &= \xi,
\end{align*}$$

where

$$\phi(\cdot) = \beta_1 \alpha \exp\left(\frac{\beta_3 + \gamma_1 u - y}{\beta_1}\right) u.$$

Remark 3.8: The SoC, represented by $x$, is always positive, also $x + \beta_2$ has to be positive if the model (16) is valid. One can verify that the state transformation (17) is a diffeomorphism over $x \in \mathbb{R}^+$, i.e., the state transformation (17) is well-defined in the domain where the model (16) is physically meaningful.

The system (18) in the observable coordinates has nonlinear parameterizations of $\alpha$ and $\gamma$. The transformed system (18) is already in the form (14), and thus no further transformation is required to perform adaptive observer design.

C. An Adaptive Observer

The transformed system (18) is in the form of (14), where

$$\phi(y, u, \dot{u}, \gamma_1, \alpha) = \beta_1 \alpha \exp\left(\frac{\beta_3 + \gamma_1 u - y}{\beta_1}\right) u + \gamma_1 \dot{u}.$$
Remark 3.9: Using the state transformation (17) also implies the differentiability of $\xi$, which requires the input current $u$ is differentiable. In addition, $\dot{u}$ has to be bounded in order to satisfy Assumption 3.2. These conditions on the input current $u$ sound restrictive from theoretical perspective, but are not really a restriction in reality. Performing observer design based on system dynamics having explicit dependence on $\dot{u}$ however indeed makes the observer sensitive to the measurement noise.

Assumption [47, Assum. (A3')] is however not satisfied because given a fixed 3-tuple $(y, u, \dot{u})$, one can easily find two sets of parameters $\rho^1$ and $\rho^2$ such that $\phi(y, u, \dot{u}, \rho^1) = \phi(y, u, \dot{u}, \rho^2)$. Notice that Assumption [47, Assum. (A3')] is not explicitly used to show the convergence, and the proof of Theorem [47, Thm. 4.2] merely relies on Assumptions (A1'),(A2'),(A4'). We may still be able to have an adaptive observer as long as Assumption [47, Assum. (A4')] is verified.

We consider the following system

$$\begin{align*}
\dot{\xi} &= \theta(y - \hat{y}) + \hat{\phi} + \theta^2 \hat{p}^T \hat{y}^T (y - \hat{y}), \\
\dot{\hat{y}} &= -\theta y + \hat{\phi} \rho, \\
\rho &= \hat{\theta} \hat{p} \hat{y}^T (y - \hat{y}) + \hat{\rho}, \\
\dot{\hat{\rho}} &= -\theta \hat{p} \hat{y} \hat{p}^T \hat{y} + \hat{\theta} \hat{p}, \quad P(0) = P_0 \in \mathbb{R}^{2 \times 2},
\end{align*}$$

(20)

where $\hat{\rho} = [\hat{\alpha}, \hat{\gamma}]^T$, $\theta$ is a sufficiently large positive constant, $\hat{\xi}_0$ is constant, $Y_0$ is bounded and constant, $P_0$ is positive definite, and

$$\frac{\partial \hat{\phi}}{\partial \rho} = \left( \frac{\partial \phi(y, u, \dot{u}, \rho)}{\partial \rho} \bigg|_{\rho = \text{sat}(\rho)} \right)^T.$$

The notation sat$(\cdot)$ performs an element-wise saturation if its argument is a vector, for instance,

$$\text{sat}(\rho) = \begin{bmatrix} \text{sat}(\hat{\alpha}) \\ \text{sat}(\hat{\gamma}) \end{bmatrix}.$$

If its argument is a scalar, the sat$(\cdot)$ operation is exemplified by the sat$(\bar{\alpha})$ as follows

$$\text{sat}(\bar{\alpha}) = \begin{cases} \bar{\alpha}, & \text{if } \bar{\alpha} \leq \bar{\alpha} \\ \bar{\alpha}, & \text{if } \bar{\alpha} \in (\bar{\alpha}, \bar{\alpha}), \\ \bar{\alpha}, & \text{if } \bar{\alpha} \geq \bar{\alpha}, \end{cases}$$

where $\bar{\alpha}$ and $\bar{\alpha}$ are the lower and upper bounds of $\alpha$. Similarly, sat$(\hat{\xi})$ and sat$(\hat{\gamma})$ saturate $\hat{\xi}$ and $\hat{\gamma}$, based on bounds of $\xi$ and $\gamma$, respectively. Given $\hat{\phi} = \phi(y, u, \dot{u}, \text{sat}(\rho))$, Assumption 3.3, when applied to the system (18), reads: the function $\phi(y, u, \dot{u}, \rho)$ is Lipschitz with respect to $\rho$, uniformly in $y$, $u$ and $\dot{u}$, i.e., (19) holds for any $\rho^1, \rho^2 \in \Omega$ and $(y, u, \dot{u}) \in \mathcal{D}$.

Remark 3.10: The term $\hat{\phi}$ can be taken as

$$\hat{\phi} = \phi(\text{sat}(\hat{\xi}), u, \dot{u}, \text{sat}(\rho)),$$

(22)

and Assumption 3.3 is modified accordingly: the function $\phi(\hat{\xi}, u, \dot{u}, \rho)$ is Lipschitz with respect to $(\hat{\xi}, \rho)$, uniformly in $u$ and $\dot{u}$, i.e., there exists a constant $L$ such that the following inequality holds

$$\|\phi(u, \dot{u}, X^1) - \phi(u, \dot{u}, X^2)\| \leq L \|X^1 - X^2\|,$$

(23)

for any $X^1 = (\xi^1, \rho^1), X^2 = (\xi^2, \rho^2) \in \mathbb{R} \times \mathbb{R}$.

As pointed out in [47], the saturation of $\hat{\xi}$ and $\hat{\rho}$ in (21) and (22) is required to apply the Lipschitz conditions, e.g. (19) and (23), which is critical in the stability proof. For the case where $\hat{\phi}$ is given by (22), although the original state and parameters are bounded in the domain $\mathbb{R} \times \mathbb{R}$, the trajectories of $\hat{\xi} \hat{\rho}$ in (20) may escape from the domain $\mathbb{R} \times \mathbb{R}$. Thus Assumption 3.3 should be extended to a large domain to prove the error dynamic stability, which is not obvious. A natural treatment is to prevent the state and parameter estimates in $\phi$ from leaving the bounded domain $\mathbb{R} \times \mathbb{R}$, by saturating the arguments $\hat{\xi}$ and $\hat{\rho}$ in (22), which consequentially guarantees the satisfaction of Assumptions 3.2-3.3. By the aforementioned saturation definition, the Lipschitz condition (23) still holds because

$$\|\phi - \hat{\phi}\| \leq L \|\hat{X} - \hat{\phi}(\hat{X})\| \leq L \|\hat{X} - \hat{X}\|,$$

where $X = (\xi, \rho)$ and $\hat{X} = (\hat{\xi}, \hat{\rho})$ for any $X \in \mathbb{R} \times \mathbb{R} \times \mathbb{R}$. Similar saturation technique has been applied to obtain the semi-globally stable estimation error dynamics in [43], [53].

Assumption [47, Assum. (A4')], restricted to system (18), is written as follows

Assumption 3.11: The input $u$ is such that for any trajectory of system (20), $y(t)$ is persistently exciting i.e., there exist $\delta_1, \delta_2, T > 0$, for any $t \geq 0$, the following inequalities hold

$$\delta_1 I_2 \leq \int_{t}^{t+T} \hat{Y}^T(t) Y(t) \mathrm{d}t \leq \delta_2 I_2,$$

(24)

where $I_2$ is the $2 \times 2$ identity matrix.

We have the following result on the adaptive observer design for system (18). Proof of Proposition 3.12 is omitted due to its similarity to that of [47, Thm. 4.2].

Proposition 3.12: Provided that $u, \dot{u}, y, \rho \in \mathcal{D}$, and the Lipschitz condition (19) and Assumption 3.11 hold, (20) with $\hat{\phi}$ given by (21) is an adaptive observer of system (16), where $\hat{\theta}$ is a sufficiently large positive constant.

Next we verify that Assumption 3.11 may still hold for (20) even if Assumption [47, Assum. (A3')] is not satisfied. The $\mathcal{Y}$-dynamics is excited by the following input

$$\frac{\partial \hat{\phi}}{\partial \rho} = \begin{bmatrix} \beta_1 \exp \left( \frac{\beta_1 \text{sat}(\hat{\gamma})}{\beta_1 - \text{sat}(\hat{\gamma})} \right) u \\ \text{sat}(\bar{\alpha}) \exp \left( \frac{\beta_1 \text{sat}(\hat{\gamma})}{\beta_1 - \text{sat}(\hat{\gamma})} \right) u^2 + \dot{u} \end{bmatrix}.$$
if assuming $\partial \phi / \partial \hat{x}$ and $\partial \hat{\phi} / \partial \hat{\gamma}$ are integrable over $[t, t+T]$ for any $t \geq 0$, we rewrite (24) as follows

$$\delta_{t} \theta^{2} l_{2} \leq \left[\frac{\partial \phi}{\partial \hat{x}} \frac{\partial \phi}{\partial \hat{h}} \right]^{T} \left[\frac{\partial \phi}{\partial \hat{x}} \frac{\partial \phi}{\partial \hat{h}} \right] \leq \delta_{t} \theta^{2} l_{2} \quad (25)$$

We can further verify that the space consisting of all integrable functions over $[t, t+T]$ for any $t \geq 0$ is a pre-Hilbert space and the inner product is a norm of the space, thus the Cauchy-Schwarz inequality holds. Denoting

$$\| \hat{x} \|^2 = \langle \hat{x}, \hat{x} \rangle = \int_{t}^{t+T} \hat{x}^{2}(t) dt,$$

we have

$$\left( \frac{\partial \phi}{\partial \hat{x}}, \frac{\partial \phi}{\partial \hat{h}} \right) \leq \left\| \frac{\partial \phi}{\partial \hat{x}} \right\| \times \left\| \frac{\partial \phi}{\partial \hat{h}} \right\|.$$

That is to say, given $\| \partial \phi / \partial \hat{x} \|$ and $\| \partial \phi / \partial \hat{h} \|$ nonzero, the matrix in (25) is not positive definite if and only if $\forall t \geq 0$, $\frac{\partial \phi(t)}{\partial \hat{x}} = k \frac{\partial \phi(t)}{\partial \hat{h}}, \forall k \in R, t \in [t, t+T]. \quad (26)$

An intuitive interpretation of (26) is that the sensitivity functions of $\phi$ with respect to parameters $\alpha$ and $\gamma$ are linearly independent, otherwise, $\alpha$ and $\gamma$ are not distinguishable.

**Remark 3.13:** The fact that [47, Assum. (A3')] does not hold for the transformed system (18) partially justifies the use of the two-stage approach for SoC and parameter estimation. For the one-stage approach where $\hat{\beta}$ is unknown parameters as well, [47, Assum. (A3')] and the PEC [47, Assum. (A4')] are much more difficult to satisfy.

A similar result to Proposition 3.12, based on a different definition of $\hat{\phi}$ and the Lipschitz condition, is given as follows.

**Proposition 3.14:** Provided that $u, \dot{u}, y \in \mathcal{D}$, and the Lipschitz condition (23) and Assumption 3.11 hold, (20) with $\hat{\phi}$ given by (22) is an adaptive observer of system (16), where $\theta$ is a sufficiently large positive constant.

**D. Alternative Adaptive Observer**

In the observer (20), the priori knowledge about the bounds of the state and parameters is used to saturate the estimates in $\hat{\phi}$ such that the error dynamic stability can be established. The observer state $\hat{\xi}$ and $\hat{\rho}$ however can unnecessarily leave the domain $Z \times \Omega$, i.e., the observer (20) does not fully exploit the priori knowledge of the state and parameter bounds. We may improve this by considering the following alternative adaptive system

$$\begin{align*}
\dot{\xi} &= \theta(y - \bar{y}) + \hat{\phi} + \theta T \text{Proj}(\kappa, \hat{\rho}), \quad \xi(0) = \xi_0 \in Z, \\
\hat{\gamma} &= -\theta Y + \frac{\partial \hat{\phi}}{\partial \hat{\rho}}, \quad Y(0) = Y_0 \in \mathbb{R}^2, \\
\dot{\hat{\rho}} &= \text{Proj}(\kappa, \hat{\rho}), \quad \hat{\rho}(0) = \hat{\rho}_0 \in \Omega, \\
\hat{P} &= -\theta PT^{T} \hat{Y} + \hat{\rho}P, \quad P(0) = P_0 \in \mathbb{R}^{2 	imes 2},
\end{align*} \quad (27)$$

where $\kappa = (\kappa_1, \kappa_2)^T = \theta PT^{T}(y - \bar{y})$, $\text{Proj}(\kappa, \hat{\rho}) = (\text{Proj}(\kappa_1, \hat{\alpha}), \text{Proj}(\kappa_1, \hat{\gamma}))^T$, and $\hat{\phi}$ is given by (21). The projection operator $\text{Proj}(\cdot, \cdot)$ is defined as follows

$$\begin{align*}
\text{Proj}(\kappa_1, \hat{\alpha}) &= \begin{cases}
0, & \text{if } \kappa_1 \leq 0 \text{ and } (\hat{\alpha} - \bar{\alpha}) \leq 0, \\
0, & \text{if } \kappa_1 \geq 0 \text{ and } (\hat{\alpha} - \bar{\alpha}) \geq 0, \\
\kappa_1, & \text{otherwise},
\end{cases} \quad (28)\\
\text{Proj}(\kappa_2, \hat{\gamma}) &= \begin{cases}
0, & \text{if } \kappa_2 \leq 0 \text{ and } (\hat{\gamma} - \bar{\gamma}) \leq 0, \\
0, & \text{if } \kappa_2 \geq 0 \text{ and } (\hat{\gamma} - \bar{\gamma}) \geq 0, \\
\kappa_2, & \text{otherwise},
\end{cases}
\end{align*}$$

where $\bar{\gamma}, \bar{\gamma}$ are lower and upper bounds of $\gamma$. The projection operator can be chosen differently, e.g. [54, Eqn. (A.25)]. We have the following result about the system (27).

**Proposition 3.15:** Provided that $u, \dot{u}, y \in \mathcal{D}$, and the Lipschitz condition (23) and Assumption 3.11 hold, the system (27) with $\hat{\phi}$ given by (21) is an adaptive observer of the system (16), where $\theta$ is a sufficiently large positive constant.

A detailed proof of Proposition 3.15 is omitted, since it is can be readily established by considering the proof of Proposition 3.12 and the following fact:

According to the proof of [47, Thm. 4.2], there exists a time-varying quadratic Lyapunov function candidate $V(t, \bar{x})$ such that its time derivative along the the error dynamics corresponding to observer (20), denoted by $\hat{V}(20)$, satisfies

$$\dot{V}(20) = \frac{\partial V}{\partial \bar{x}} + \frac{\partial V}{\partial \bar{\gamma}} \tilde{f}(20) \leq -k_4 V,$$

where $\bar{x}$ is the estimation error, $\tilde{f}(20)$ is the estimation error dynamics corresponding to (20), and $k_4 > 0$. Next we show that the time derivative of $V$ along the error dynamics corresponding to observer (27), denoted by $\dot{V}(27)$, is upper-bounded by $\hat{V}(20)$, i.e., that satisfies the following inequality

$$\dot{V}(27) \leq \hat{V}(20) \leq -k_4 V.$$

Essentially, we need to show

$$\frac{\partial V}{\partial \bar{x}} \tilde{f}(27) \leq \frac{\partial V}{\partial \bar{x}} \tilde{f}(20), \quad (30)$$

where $\tilde{f}(27)$ is the estimation error dynamics corresponding to (27). Since $V$ is a time-varying and quadratic function of estimation errors, we take a Lyapunov function $V_\alpha = 0.5(\alpha - \bar{\alpha})^2$ as an example to illustrate the proof. We have the time derivative of $V_\alpha$ along (27)

$$\dot{V}_\alpha = k_1(\alpha - \bar{\alpha}) \kappa_1 \alpha = \begin{cases}
0, & \text{if } \kappa_1 \leq 0 \text{ and } (\alpha - \bar{\alpha}) \leq 0, \\
0, & \text{if } \kappa_1 \geq 0 \text{ and } (\alpha - \bar{\alpha}) \leq 0, \\
k_1(\alpha - \bar{\alpha}) \kappa_1, & \text{otherwise}.
\end{cases}$$

With the same Lyapunov function, its time derivative along (20) is

$$\dot{V}_\alpha = k_1(\alpha - \bar{\alpha}) \kappa_1 \alpha = \begin{cases}
\geq 0, & \text{if } \kappa_1 \leq 0 \text{ and } (\alpha - \bar{\alpha}) \leq 0, \\
\geq 0, & \text{if } \kappa_1 \geq 0 \text{ and } (\alpha - \bar{\alpha}) \leq 0, \\
k_1(\alpha - \bar{\alpha}) \kappa_1, & \text{otherwise}.
\end{cases}$$

We know

$$\dot{V}_\alpha \leq \hat{V}_\alpha. \quad (31)$$

This fact holds for the estimation errors $\hat{\xi} - \bar{\xi}$ and $\hat{\gamma} - \bar{\gamma}$. We therefore prove (30). We therefore conclude that the adaptive observer (27) also yields exponentially stable error dynamics.
Remark 3.16: Assumption 3.11 imposes different constraints on the systems (20) and (27), respectively. That is to say, the satisfaction of Assumption 3.11 for the system (20) does not necessarily concur with its satisfaction for the system (27).

Similar to Proposition 3.15, we have the following statement.

Proposition 3.17: Provided that \( u, \dot{u}, y \in \mathcal{C} \), and the Lipschitz condition (23) and Assumption 3.11 hold, the system (27) with \( \hat{\phi} \) given by (22) is an adaptive observer of the system (16), where \( \theta \) is a sufficiently large positive constant.

Remark 3.18: Another form of adaptive observer can be taken by applying projection operator to the right hand side of the dynamic equation of \( \hat{x} \), i.e., the first equation of (27) is replaced with the following equation

\[
\dot{\hat{x}} = \text{Proj}(\psi, \hat{x}),
\]

where \( \psi = \theta(y - \hat{y}) + \hat{\phi} + \theta \text{Proj}(\kappa, \hat{\rho}) \). Error dynamics stability can be established by using the same technique as in the sketched proof of Proposition 3.15.

E. Robustness and Applicability

Given Assumption 3.11, both of adaptive observers (20) and (27) yield error dynamics of the state and parameter estimation which are exponentially convergent. We analyze the robustness of the adaptive observer (20) with respect to the process model uncertainty and the measurement noise. The adaptive observer (27) enjoys similar robustness property as (20) thus its analysis is omitted.

Robustness analysis is performed based on the input-state-stability (ISS) [55, Def. 4.7]. To facilitate the analysis, we introduce the notation of estimation errors: \( \tilde{x} = X - \hat{X} \). Given the system (18) and the adaptive observer (20), it is not difficult to derive that the error dynamics can be written as follows

\[
\dot{\tilde{x}} = \tilde{f}(y, u, \dot{u}, \text{sat}(\tilde{\xi}), \text{sat}(\hat{\rho}), \theta, Y, P, \tilde{X}),
\]

where \( y, u, \dot{u}, \text{sat}(\tilde{\xi}), \text{sat}(\hat{\rho}), \theta, Y, P \) are bounded. Considering \( \tilde{f} \) is continuously differentiable and \( \varphi \) is Lipschitz over \( \mathcal{C} \), we know that \( \partial \tilde{f}/\partial \tilde{X} \) is bounded over \( Z \times W \), uniformly in \( y, u, \dot{u}, \text{sat}(\tilde{\xi}), \text{sat}(\hat{\rho}), \theta, Y, P \). Also since the zero solution of the \( \tilde{x} \)-dynamics is exponentially stable, [55, Thm. 4.14] applies, i.e., there exists a function \( V(r, \tilde{X}) \) satisfying the inequalities:

\[
\begin{align*}
\frac{c_1}{\|\tilde{X}\|^2} \leq V & \leq \frac{c_2}{\|\tilde{X}\|^2}, \\
\frac{\partial V}{\partial t} + \frac{\partial V}{\partial \tilde{X}} \tilde{f} & \leq -c_3 \|\tilde{X}\|^2, \\
\left\|\frac{\partial V}{\partial \tilde{X}}\right\| & \leq c_4 \|\tilde{X}\|,
\end{align*}
\]

where \( c_1, 1 \leq i \leq 4 \) are positive constants. Now assume instead of (16), the true battery model is given by

\[
\begin{align*}
\dot{x} &= \alpha u + d(t), \\
y &= \beta_1 \log(x + \beta_2) + \beta_3 + \gamma u + n(t),
\end{align*}
\]

where \( d(t) \) is bounded and represents the unmodeled process dynamics, and \( n(t) \) is continuously differentiable and represents the measurement noise. Under the new coordinates defined by (17), the system (33) is rewritten as follows

\[
\begin{align*}
\dot{\tilde{x}} &= \varphi(y - n(t), u, \dot{u}, \rho) + d(t), \\
y &= \xi + n(t),
\end{align*}
\]

With adaptive observer (20), the resultant error dynamics are

\[
\dot{\tilde{x}} = \tilde{f}(y - n(t), u, \dot{u}, \text{sat}(\tilde{\xi}), \text{sat}(\hat{\rho}), \theta, Y, P, \tilde{X}) + En(t) + Fd(t),
\]

where

\[
E = \begin{bmatrix} \theta + \theta^2 Y P^T \theta P Y^T \end{bmatrix} \in \mathbb{R}^3, \quad F = \begin{bmatrix} 1 & 0 & 0 \end{bmatrix}.
\]

Assuming inequalities (32) still hold with \( \tilde{f} \) replaced by \( \tilde{f}_u \), we have

\[
\dot{\tilde{V}} = \frac{\partial V}{\partial t} + \frac{\partial V}{\partial \tilde{X}} (\tilde{f}_u + En(t) + Fd(t))
\]

\[
\leq -c_3 \|\tilde{X}\|^2 + c_4 \|\tilde{X}\| \cdot (\|En(t) + Fd(t)\|),
\]

\[
\leq -c_3 \|\tilde{X}\|^2 + c_4 \|\tilde{X}\| \cdot (\|E\| \cdot \|n(t)\|_\infty + \|F\| \cdot \|d(t)\|_\infty)
\]

\[
\leq -c_3 \|\tilde{X}\|^2 + c_4 \theta \|n(t)\|_\infty \cdot \|\tilde{X}\| + c_4 \|d(t)\|_\infty \cdot \|\tilde{X}\|,
\]

where \( c_3 \) is positive, and \( \|n(t)\|_\infty, \|d(t)\|_\infty \) are the infinity norm of signals \( n(t) \) and \( d(t) \), respectively. From the expression of \( \dot{\tilde{V}} \), we have the following conclusions

1) The error dynamics are ISS with respect to unmodeled process dynamics and the measurement noise, i.e., given bounded unmodeled process dynamics \( d(t) \) and the measurement noise \( n(t) \), the estimation error is bounded.

2) Since \( c_3 \) is a function of \( \theta \), the term \( c_4 \theta \|n(t)\|_\infty \cdot \|\tilde{X}\| \), due to the measurement noise, could be quite large. On the other hand, the term \( c_4 \|d(t)\|_\infty \cdot \|\tilde{X}\| \), due to the unmodeled process dynamics, is independent from \( \theta \). Hence, the adaptive observer (20) is more robust to the unmodeled process dynamics than to the measurement noise. This is not surprising due to the high gain essence of the adaptive observer (20).

3) The adaptive observer (27) is more robust with respect to the measurement noise than (20) because the adaptive law in (20), i.e., the \( \hat{\rho} \)-dynamics, do not use the projection operator, thus the term \( \theta^2 Y P^T \theta P Y^T \) always appears in the \( \tilde{\xi} \)-dynamics. Instead, for the adaptive observer (27), during the period of \( \text{Proj}(\kappa, \hat{\rho}) = 0 \), the term \( \theta^2 Y P^T \theta P Y^T \), representing the effect of the measurement noise, is absent from the \( \tilde{\xi} \)-dynamics.

4) There exists a tradeoff between the convergence rate of the error dynamics and the robustness with respect to the measurement noise. Given the PEC satisfied for some \( \delta_1, \delta_2 \) and a sufficiently large \( \theta \), a larger \( \theta \), from theoretical perspective, leads to faster convergence at the expense of more sensitivity to the measurement noise. Making the gain \( \theta \) time varying might help to improve the transience of the error dynamics, for instance, adjusting the gain \( \theta \) according to the amplitude of the estimation error \( y - \hat{y} \).

Both of adaptive observers (20) and (27) rely on the transformed system (18), which implies continuous differentiability.
of the transformed state $\xi$. Equivalently both the adaptive observers (20) and (27) assume the continuous differentiability of the terminal voltage. This assumption may not be valid in certain scenarios. For instance, the input current $u$ may not be differentiable or even continuous, so does the terminal voltage.

The system's failure to satisfy the differentiability prerequisite does not mean the adaptive observers (20) and (27) are not applicable to that system. The adaptive observer (20) or (27) is essentially an filter which tries to track the terminal voltage. The discontinuities in the terminal voltage can be viewed as various step inputs at different time instants. Since the filter has a limited bandwidth controlled by the gain $\theta$, it cannot track the step input perfectly and a transient response of the estimated terminal voltage is resulted. Since the terminal voltage estimation is clearly not accurate, thus the SoC and parameter estimates deviate from the true values during the transience. The applicability of the proposed adaptive observers can be summarized as follows:

1) The proposed approach is applicable for the cases where the terminal voltage is continuously differentiable. This scenario includes applications where the charge and discharge processes are completely separate. For instance, portable electronic devices. For these applications, the proposed approach leads to an adaptive observer which provides reliable estimation of both the SoC for control and parameters for battery diagnosis.

2) Similarly, the proposed approach is applicable to cases where charge and discharge periods are much longer than the transient period due to jumps in the terminal voltage. Note that the transient period can be made arbitrarily small, theoretically, by choosing a sufficiently large observer gain $\theta$. In practice this is not possible because of the design tradeoff between the gain $\theta$ and the noise level of the measurements, and the constraint on $\theta$ to satisfy the PEC. Measurements with higher resolution and quality allow a larger $\theta$ which leads to a shorter transient time. A variable gain strategy, for instance based on the amplitude of the estimation error of the terminal voltage, however could relax the fundamental limitation.

3) The proposed approach can complement other auxiliary estimators, which are insensitive to jumps in the input current, to produce a good estimate. Such an auxiliary estimator can be based on Coulomb counting or Kalman Filtering.

It is worth pointing out that the proposed approach is generic and not limited to the specific model (12). Generalization of the proposed approach to other models might also be possible, for instance equivalent circuit models with or without the hysteresis voltage as a state variable.

F. A Switched Adaptive Observer

This section includes a brief illustration of the adaptive SoC estimation based on the switched battery model (11). Similar to the procedure in Section III-C, we introduce state transformations $\xi_1 = h(x, \bar{\beta}) + g(u, \gamma)$ and $\xi_2 = h(x, \bar{\beta}) + g(u, \gamma)$ corresponding to discharge and charge modes, respectively, and have the transformed system given by

$$
\begin{align*}
\Sigma_d: & \begin{cases} 
\dot{\xi}_1 = \varphi_1(\cdot, \bar{\beta}), & t \geq t_i, \\
y = \xi_1,
\end{cases} \\
\Sigma_c: & \begin{cases} 
\dot{\xi}_2 = \varphi_2(\cdot, \bar{\beta}), & t \geq t_j, \\
y = \xi_2,
\end{cases}
\end{align*}
$$

where $t_i, t_j$ are the time instants when the sign of $u$ changes. To enforce the continuity of the SoC, we allow jumps of the state $\xi_1$ or $\xi_2$ at switch times $t_i$ and $t_j$, i.e., the following switch conditions hold

$$
\begin{align*}
\xi_1(t_i^+) = h(x(t_i^-), \bar{\beta}) + g(u(t_i^-), \gamma(t_i^-)), \\
\xi_2(t_j^+) = h(x(t_j^-), \bar{\beta}) + g(u(t_j^-), \gamma(t_j^-)).
\end{align*}
$$

The system (35) is impulsive and the observer design for these systems is out of main focus of this paper. Given system (35)-(36), one can apply the proposed approach to $\Sigma_d$ and $\Sigma_c$ respectively. If $u$ switches sign slowly enough, the stability results in Propositions 3.12-3.15 can be similarly established for the adaptive system consisting of two adaptive observers which are designed on the basis of $\Sigma_d$ and $\Sigma_c$, respectively.

IV. EXAMPLES

A. Simulation

Consider the battery model (10) and assume that there is no mismatch between the model and the battery dynamics. The model parameters are given as follows: $\alpha = 4.7496 \times 10^{-5}$, $\beta_1 = 1.0480$, $\beta_2 = 0.2208$, $\beta_3 = 3.9998$, $\gamma_1 = -5 \times 10^{-3}$. Here, the values of $\alpha$ and $\gamma_1$ are reckoned according to [24], [25], [56] and may have little applicability to a specific battery. The values of $\beta_i$'s are determined by fitting the SoC-OCV data of the battery from experiments. The input to the model is a sinusoid wave $u = 10 \sin(10t)$. We take $\theta = 20$ and the following initial conditions (ICs)

$$
\begin{align*}
\xi(0) &= 0.5; & \dot{\xi}(0) &= 0; \\
\gamma(0) &= (0, 0), & \dot{\gamma}(0) &= (0, 0)^T, & P(0) &= I_2.
\end{align*}
$$

Simulation results are given in Figures 3-5, which show that adaptive observer (20) can provide convergent estimation of the transformed system state and parameters. This further implies the state of the original system (16), or the SoC, can also be estimated exponentially. We also verify that the adaptive observer provides convergent estimation of the SoC and parameters over a fairly large domain. Details are omitted due to space limitation. Interested readers are referred to [22] for details.

B. Experiment

The experimental validation of the proposed approach is given as follows. For the case where the adaptive SoC estimation is performed based on the adaptive observer (20) and the model (10), we use both charge and discharge curves to identify parameters $\bar{\beta}$ in $h(x, \bar{\beta})$. For the case where the adaptive SoC estimation is performed based on adaptive observer (27) and the switched model (11), we use the charge and discharge curves to identify parameters $\bar{\beta}$ and $\bar{\beta}$, respectively. Both the
charge and discharge curves depict the relationship between the SoC and the terminal voltage of the battery in charge and discharge modes, respectively, where the SoC is obtained by coulomb counting. Instead of having the battery rest for a long time to measure the OCV, we measure the terminal voltage continuously as the battery is in charge or discharge modes. Particularly, the charge curve is obtained by applying a small charge current to the battery and the discharge curve is obtained by applying a small discharge current to the battery.

The rest experiment to validate the SoC estimation algorithm is conventional. That is: the battery is subject to a charge and discharge current; both the current and the terminal voltage are measured. The input current profile is shown in Figure 6. The battery has a nominal capacity 4.903Ah. The input current and terminal voltage are sampled every second. Thus the nominal value of the parameter $\alpha$ is $5.63421 \times 10^{-5}$. The ICs of adaptive observers are taken as follows

$$\hat{\xi}(0) = 3, \quad \Upsilon(0) = (0, 0), \quad \hat{\rho}(0) = (0, 0)^T, \quad P(0) = I_2. \quad (37)$$

The gain tuning parameter $\theta$ is taken as 0.08 for adaptive observer (20) and 0.025 for adaptive observer (27). The validation results are shown in Figures 6-10, where red solid lines correspond to results of adaptive observer (20) and the black line corresponds to adaptive observer (27). The transformed system state, the state estimate, and their error are shown in Figure 7. Overall the state estimate $\hat{\xi}$ tracks the true state $\xi$ except spikes at time instants when the input current jumps. It is worth pointing out that the estimation error approaches zero over time interval between two adjacent current jumps.

The estimation of the parameter $\alpha$ is shown in Figure 8, where the blue solid line represents the nominal value of $\alpha$. Consistent with the trajectory of the state estimation error $\xi - \hat{\xi}$, the trajectory of $\hat{\alpha}$ has spikes when the current changes directions. The appearance of spikes in $\hat{\alpha}$ is understood because the proposed adaptive observer updates its estimates according to the spiky output error $\xi - \hat{\xi}$. The spikes in the trajectory of $\xi - \hat{\xi}$, interpreted as step inputs into the adaptive observer, necessarily induce spikes in $\hat{\alpha}$. Although the
amplitude of $\hat{\alpha}$ around spikes may be several times larger than the nominal value of $\alpha$, the trajectory of $\hat{\alpha}$ seems convergent to some extent during the interval between jumps, and is still useful. This is because the trajectory of $\hat{\alpha}$ stays in a small neighborhood of the nominal value at most of time, and functions of $\hat{\alpha}$, e.g. the mean value, might indicate the State of Health in the long run. The estimation of the parameter $\gamma_1$ is given in Figure 9. Again the parameter estimate $\hat{\gamma}_1$ has spikes. It should be realized that the estimate $\hat{\gamma}_1$ is not so valuable during periods with zero input current, because the effect of $\gamma_1$ is literally ignored by the model. If we ignore those zero current intervals, it is not difficult to see that during the intervals between two adjacent current jumps, the $\hat{\gamma}_1$ trajectory approaches to some value between 2.5m-Ohm and 3m-Ohm. Overall, the estimate $\hat{\gamma}_1$ is quite reasonable in the sense that the average of the estimate trajectory has a small variation.

Fig. 7. The transformed system state $\xi$ and its estimation $\hat{\xi}$

Fig. 8. Estimate of the parameter $\alpha$

The estimates of the SoC using Coulomb counting and the proposed approach are presented in Figures 10, where the red solid line is the SoC estimate produced by adaptive observer (20) designed based on (18), and the black solid line is the SoC estimate produced by adaptive observer (27) designed based on (35). The implemented adaptive observer (27) however still enforces the continuity of the terminal voltage instead of the SoC. This is to examine how the introduction of the hysteresis in the OCV-SoC curve can improve the accuracy of the SoC estimation. Consistent with trajectories of the state and parameter estimates, the estimated SoC trajectory also has spikes which at the worst case could shoot up to 10% for the case ignoring hysteresis. A number of factors contribute to the appearance of spikes. First factor is the presence of the discontinuity of the input current. We illustrate this by considering the scenario where the input current switches from non-zero to zero at time $t_1$. At time $t^-_1$, the terminal voltage is $y(t^-_1) = OCV(t^-_1) + \gamma_1 u(t^-_1)$; at the time instant $t^+_1$, the terminal voltage is $y(t^+_1) = OCV(t^+_1)$. Since the proposed approach assumes the continuity of the terminal voltage, i.e.,

$$y(t^-_1) = OCV(t^-_1) + \gamma_1 u(t^-_1) = y(t^+_1) = OCV(t^+_1),$$

the OCV, consequently the SoC, at $t^+_1$ has to be discontinuous.

Fig. 9. Estimate of the parameter $\gamma_1$

Fig. 10. SoC estimates $\hat{\text{SoC}}$ using various methods
In the experiment, the amplitude of the current is around 50A. Given $\gamma_1 = 2.5\text{m-Ohm}$, the jump of OCV from $i^-_1$ to $i^+_1$ will be $\pm 0.125\text{Volts}$. According to the average SoC-OCV curve, variations of the OCV with such an amplitude corresponds to around 5-10% variation of the SoC. In a realistic scenario, it is unlikely that the input current is discontinuous thus the proposed algorithm might be still applicable. One solution to this issue is to modify the proposed algorithm to be free of time derivative.

The second factor is the model mismatch, i.e., the model (10) fails to capture the RCE, the RE, and the HE. The HE on the SoC estimation has been alleviated by applying the proposed approach to the switched battery model (11). As shown in Figure 10, the SoC estimation error corresponding to the switched model is within 4.5%. Further improvement of the SoC estimation accuracy by enforcing the continuity of the SoC is possible.

V. CONCLUSION AND FUTURE WORK

This paper considered adaptive State of Charge (SoC) and parameter estimation of Lithium-ion batteries. A well-established nonlinear geometric observer approach was applied to simplified and nonlinear battery models for estimating the SoC and parameters. The resultant error dynamics of state and parameter estimation are exponentially convergent under the model matching condition. The proposed adaptive observers were shown robust to process uncertainties. Robustness analysis also indicated the design tradeoff between the convergence rate of the error dynamics and robustness to the measurement noise. Simulation and experiments were carried out to validate the effectiveness and main advantages of the proposed approach: capability to provide relatively reliable estimates of the SoC and parameters. Experiments also revealed that the proposed approach may not work well if the input current has many discontinuous points. Error analysis was presented to explain experimental results. Future work will focus on the modification of the proposed algorithm to be free of input derivative, and its generalization to other models.
