Parallel proximal methods for total variation minimization

Kamilov, U.

TR2016-007 March 2016

Abstract

Total variation (TV) is a widely used regularizer for stabilizing the solution of ill-posed inverse problems. In this paper, we propose a novel proximal-gradient algorithm for minimizing TV regularized least-squares cost functional. Our method replaces the standard proximal step of TV by a simpler alternative that computes several independent proximals. We prove that the proposed parallel proximal method converges to the TV solution, while requiring no sub-iterations. The results in this paper could enhance the applicability of TV for solving very large scale imaging inverse problems.

PARALLEL PROXIMAL METHODS FOR TOTAL VARIATION MINIMIZATION

ABSTRACT
Total variation (TV) is a widely used regularizer for stabilizing the solution of ill-posed inverse problems. In this paper, we propose a novel proximal-gradient algorithm for minimizing TV regularized least-squares cost functional. Our method replaces the standard proximal step of TV by a simpler alternative that computes several independent proximals. We prove that the proposed parallel proximal method converges to the TV solution, while requiring no sub-iterations. The results in this paper could enhance the applicability of TV for solving very large scale imaging inverse problems.

1. INTRODUCTION
The problem of estimating an unknown signal from noisy linear observations is fundamental in signal processing. The estimation task is often formulated as the linear inverse problem

$$y = Hx + e,$$  \hspace{1cm} (1)

where the goal is to compute the unknown signal $x \in \mathbb{R}^N$ from the noisy measurements $y \in \mathbb{R}^M$. Here, the matrix $H \in \mathbb{R}^{M \times N}$ models the response of the acquisition device and the vector $e \in \mathbb{R}^M$ represents the measurement noise, which is often assumed to be i.i.d. Gaussian. When the problem (1) is ill-posed, the standard approach is to rely on the regularized least-squares estimator

$$\hat{x} = \arg \min_{x \in \mathbb{R}^N} \left\{ \frac{1}{2} \|y - Hx\|_2^2 + \mathcal{R}(x) \right\},$$  \hspace{1cm} (2)

where the functional $\mathcal{R}$ is a regularizer that promotes solutions with desirable properties such as transform-domain sparsity or positivity.

One of the most widely used regularizers in imaging is the total variation (TV), whose anisotropic variant can be defined as

$$\mathcal{R}(x) \triangleq \lambda \|Dx\|_{\ell_1} = \lambda \sum_{n=1}^N \sum_{d=1}^D |D_d x|_n,$$  \hspace{1cm} (3)

where $D : \mathbb{R}^N \rightarrow \mathbb{R}^{N \times D}$ is the discrete gradient operator, $\lambda > 0$ is a parameter controlling amount of regularization, and $D$ is the number of dimensions in the signal. The matrix $D_d$ denotes the finite difference operation along the dimension $d$ with appropriate boundary conditions (periodization, etc.). The TV prior has been originally introduced by Rudin et al. [1] as a regularization approach capable of removing noise, while preserving image edges. It is often interpreted as a sparsity-promoting $\ell_1$-penalty on the image gradient. TV regularization has proven to be successful in a wide range of applications in the context of sparse recovery of images from incomplete or corrupted measurements [2–8].

The minimization (2) with the TV regularization is a non-trivial optimization task. The challenging aspects are the non-smooth nature of the regularization term (3) and the massive quantity of data that typically needs to be processed. Proximal gradient methods [9] such as iterative shrinkage/thresholding algorithm (ISTA) [10–14] or alternating direction method of multipliers (ADMM) [15–17] are standard approaches to circumvent the non-smoothness of the TV regularizer.

For the optimization problem (2), ISTA can be written as

$$z^t \leftarrow z^{t-1} - \gamma_t H^T (H z^{t-1} - y)$$  \hspace{1cm} (4a)

$$x^t \leftarrow \text{prox}_{\gamma_t \mathcal{R}} (z^t),$$  \hspace{1cm} (4b)

where $\gamma_t > 0$ is a step-size that can be determined a priori to ensure convergence [14]. Iteration (4) combines the gradient-descent step (4a) with a proximal operation (4b) defined as

$$\text{prox}_{\gamma \mathcal{R}}(z) \triangleq \arg \min_{x \in \mathbb{R}^N} \left\{ \frac{1}{2} \|x - z\|_2^2 + \gamma \mathcal{R}(x) \right\}. $$  \hspace{1cm} (5)

The proximal operator corresponds to the regularized solution of the denoising problem where $H$ is an identity. Because of its simplicity, ISTA and its accelerated variants are among the methods of choice for solving practical linear inverse problems [13, 14]. Nonetheless, ISTA–based optimization of TV is complicated by the fact that the corresponding proximal operator does not admit a closed form solution. Practical implementations rely on computational solutions that require an additional nested optimization algorithm for evaluating the TV proximal [17, 18]. This typically leads to a prohibitively
slow reconstruction when dealing with very large scale imaging problems such as the ones in 3D microscopy [8].

In this paper, we propose a novel approach for solving TV–based imaging problems that requires no nested iterations. This is achieved by substituting the proximal of TV with an alternative that amounts to evaluating several simpler proximal operators. One of our major contributions is the proof that the approach can achieve the true TV solution with arbitrarily high precision. We believe that the results presented in this paper are useful to practitioners working with very large scale problems that are common in 3D imaging, where the bottleneck is often in the evaluation of the TV proximal.

2. MAIN RESULTS

In this section, we present our main results. We start by introducing the proposed approach and then follow up by analyzing its convergence.

2.1. General formulation

We turn our attention to a more general optimization problem

$$\hat{x} = \arg \min_{x \in \mathbb{R}^N} \{C(x)\},$$

(6)

where the cost functional is of the following form

$$C(x) = D(x) + R(x) = D(x) + \frac{1}{K} \sum_{k=1}^{K} R_k(x).$$

(7)

The precise connection between (7) and TV-regularized cost functional will be discussed shortly. We assume that the data-fidelity term $D$ is convex and differentiable with a Lipschitz continuous gradient. This means that there exists a constant $L > 0$ such that, for all $x, z \in \mathbb{R}^N$, $\|\nabla D(x) - \nabla D(z)\|_2 \leq L \|x - z\|_2$. We also assume that each $R_k$ is a continuous, convex function that is possibly nondifferentiable and that the optimal value $C^*$ is finite and attained at $x^*$.

We consider parallel proximal algorithms that have the following form

$$\begin{align*}
z^t & \leftarrow x^{t-1} - \gamma_t \nabla D(x^{t-1}) \\
x^t & \leftarrow \frac{1}{K} \sum_{k=1}^{K} \operatorname{prox}_{\gamma_t R_k}(z^t),
\end{align*}$$

(8a)

(8b)

where $\operatorname{prox}_{\gamma_t R_k}$ is the proximal operator associated with $\gamma_t R_k$. We are specifically interested in the case where the proximals $\operatorname{prox}_{\gamma_t R_k}$ have a closed form, in which case they are preferable to the computation of the full proximal $\operatorname{prox}_{\gamma_t R}$.

We now establish a connection between (7) and TV-regularized cost. Define a linear transform $W : \mathbb{R}^N \rightarrow \mathbb{R}^N \times D \times 2^N$ that consists of two sub-operators: the averaging operator $A : \mathbb{R}^N \rightarrow \mathbb{R}^{N \times D}$ and the discrete gradient $D$ as in (3), both normalized by $1/\sqrt{2}$. The averaging operator consists of $D$ matrices $A_d$ that denote the pairwise averaging along the dimension $d$. Accordingly, the operator $W$ is a union of scaled and shifted discrete Haar wavelet and scaling functions along each dimension [19]. Since we consider all possible shifts along each dimension the transform is redundant and can be interpreted as the union of $K = 2D$, scaled, orthogonal transforms

$$W = \begin{bmatrix}
W_1 \\
\vdots \\
W_K
\end{bmatrix}.$$  

(9)

The transform $W$ and its pseudo-inverse

$$W^\dagger = \frac{1}{K} [W_1^T \ldots W_K^T]$$

(10)

satisfy the following two properties of Parseval frames [20]

$$\arg \min_{x \in \mathbb{R}^N} \left\{ \frac{1}{2} \|z - Wx\|_{\ell_2^2} \right\} = W^\dagger z \quad (\text{for all } z \in \mathbb{R}^{KN})$$

and

$$W^\dagger W = I.$$  

(11)

One can thus express the TV regularizer as the following sum

$$R(x) = \lambda \sqrt{2} \sum_{k=1}^{K} \sum_{n \in H_k} \|W_k x_n\|,$$

(12)

where $H_k \subseteq [1 \ldots N]$ is the set of all detail coefficients of the transform $W_k$. Then, the proposed parallel proximal algorithm for TV can be expressed as follows

$$\begin{align*}
z^t & \leftarrow x^{t-1} - \gamma_t H^T (Hx^{t-1} - y) \\
x^t & \leftarrow \frac{1}{K} \sum_{k=1}^{K} W_k^T \mathcal{T}(W_k z^t; \sqrt{2} K \gamma_t \lambda),
\end{align*}$$

(13a)

(13b)

where $\mathcal{T}$ is the component-wise shrinkage function

$$\mathcal{T}(y; \tau) \triangleq \max\{||y| - \tau, 0\} \frac{y}{|y|},$$

(14)

which is applied only on scaled differences $Dz^t$.

The algorithm in (13) is closely related to a technique called cycle spinning [21] that is commonly used for improving the performance of wavelet-domain denoising. In particular, when $H = I$ and $\gamma_t = 1$, for all $t = 1, 2, \ldots$, the algorithm yields the solution

$$\hat{x} \leftarrow W^\dagger \mathcal{T}(Wy; \sqrt{2} K \lambda),$$

(15)

which can be interpreted as the traditional cycle spinning algorithm restricted to the Haar wavelet-transform. In the context of image denoising, the connections between TV and cycle-spinning were originally established in [22].
2.2. Theoretical convergence

The convergence results in this section assume that the gradient of \( D \) and subgradients of \( R_k \) are bounded, i.e., there exists \( G > 0 \) such that for all \( k \) and \( t \), \( \| \nabla D(x^t) \|_{L_2} \leq G \) and \( \| \partial R_k(x^t) \|_{L_2} \leq G \). The following proposition is crucial for establishing the convergence of the parallel proximal algorithm.

**Proposition 1.** Consider the cost function (7) and the algorithm (8). Then, for all \( t = 1, 2, \ldots, \) and for any \( x \in \mathbb{R}^N \), we have

\[
C(x^t) - C(x) \leq \frac{1}{2\gamma_t} (\|x^{t-1} - x\|_{L_2}^2 - \|x^t - x\|_{L_2}^2) + 8\gamma_t G^2.
\]

**Proof:** See Appendix.

Proposition 1 allows us to develop various types of convergence results. For example, if \( x^* \) is the optimal point and if we pick a sufficiently small step \( \gamma_t \leq (C(x^*) - C(x^*))/(8G^2) \), then the \( x^t \) will be closer to \( x^* \) than \( x^{t-1} \). This argument can be formalized into the following proposition.

**Proposition 2.** Assume a fixed step size \( \gamma_t = \gamma > 0 \). Then, we have that

\[
\liminf_{t \to \infty} (C(x^t) - C^*) \leq 8\gamma G^2.
\]

**Proof:** See Appendix.

Proposition 2 states that for a constant step-size, convergence can be established to the neighborhood of the optimum, which can be made arbitrarily close to 0 by letting \( \gamma \to 0 \).

3. EXPERIMENTS

In this section, we empirically illustrate that our results hold more generally than suggested by Proposition 2. Specifically, we consider the accelerated parallel proximal algorithm based on FISTA [14]

\[
\begin{aligned}
z^t &\leftarrow u^{t-1} - \gamma_t \nabla D(u^{t-1}) \\
x^t &\leftarrow \frac{1}{K} \sum_{k=1}^{K} \text{prox}_{\frac{\gamma_t}{\lambda} R_k}(z^t) \\
q_t &\leftarrow (1 + \sqrt{1 + 4q_{t-1}^2})/2 \\
u^t &\leftarrow x^t + (q_{t-1} - 1)/q_t(x^t - x^{t-1})
\end{aligned}
\]

with \( u^0 = x^0, q_0 = 1, \) and \( \gamma_t = \gamma \). Method (18) preserves the simplicity of the ISTA approach (8) but provides a significantly better rate of convergence, which enhances potential applicability of the method. We consider an estimation problem where the Shepp-Logan phantom of size 32 \times 32 is reconstructed from \( M = 512 \) linear measurements with AWGN corresponding to 30 dB SNR. The measurement matrix is i.i.d. Gaussian \( [H]_{mn} \sim \mathcal{N}(0, 1/M) \). Figure 1 illustrates the per-iteration gap \( (C(x^t) - C^*)/C^* \), where \( x^t \) is computed with the fast parallel proximal method (18) and \( C \) is the TV-regularized least-squares cost. The regularization parameter \( \lambda \) was manually selected for the optimal SNR performance of TV. We compare 3 different step-sizes \( \gamma = 1/L, \gamma = 1/(4L), \) and \( \gamma = 1/(16L) \), where \( L = \lambda_{\text{max}}(H^T H) \) is the Lipschitz constant. Proposition 2 suggests that the gap \( (C(x^t) - C^*) \) is proportional to the step-size and shrinks to 0 as the step-size is reduced. Such behavior is clearly observed in Figure 1, which suggests that our results potentially hold for the accelerated parallel proximal algorithm. Figure 2 compares the quality of the estimated images, for \( \gamma = 1/L \) and \( \gamma = 1/(16L) \), against the TV solution. We note that, even for \( \gamma = 1/L \), the solution of our algorithm is very close to the true TV result, both qualitatively and quantitatively. This implies that, while requiring no nested iterations, our parallel proximal approach can potentially approximate the solution of TV with arbitrarily accurate precision at \( O(1/t^2) \) convergence rate of FISTA.
We now prove the propositions in Section 2.2. The formalism used here is closely related to the analysis of incremental proximal methods that were studied by Bertsekas [23]. Related techniques were also used to analyze the convergence of recursive cycle spinning algorithm in [24].

6.1. Proof of Proposition 1

We define an intermediate quantity \( x_k^t \triangleq \text{prox}_{\gamma R_k}(z^t) \). The optimality conditions for (8b) imply that there exist \( K \) subgradient vectors \( \nabla R_k(x_k^t) \in \partial R_k(x_k^t) \) such that

\[
x_k^t = x_k^{t-1} - \gamma_t \left[ \nabla D(x_k^{t-1}) + \nabla R_k(x_k^t) \right].
\]

This implies that

\[
x^t = x^t - \gamma_t \left[ \nabla D(x^t) + \nabla R_k(x_k^t) \right],
\]

where

\[
g^t \triangleq \frac{1}{K} \sum_{k=1}^{K} \nabla R_k(x_k^t).
\]

Then we can write

\[
\|x^t - x\|_{\ell_2}^2 = \|x^t - x^t - \gamma_t (\nabla D(x^{t-1}) + g^t) + x\|_{\ell_2}^2
\]

\[
= \|x^t - x\|_{\ell_2}^2 - 2\gamma_t (\nabla D(x^{t-1}) + g^t, x^t - x) + \gamma_t^2 \|\nabla D(x^t) + g^t\|_{\ell_2}^2.
\]

By using the triangle inequality and noting that all the subgradients are bounded, we can bound the last term as

\[
\|\nabla D(x^t) + g^t\|_{\ell_2}^2 \leq 4G^2.
\]

To bound the second term we proceed in two steps. We first write that

\[
\langle \nabla D(x), x^t - x \rangle \geq D(x^t) - D(x) \geq D(x^t) - (\nabla D(x^t), x^t - x^t - \gamma_t) - D(x) \geq D(x^t) - D(x) - 2\gamma_t G^2
\]

where we used the convexity of \( D \), the Cauchy-Schwarz inequality, and the bound on the gradients. In a similar way, we can write that

\[
\langle g^t, x^t - x \rangle = \frac{1}{K} \sum_{k=1}^{K} \langle \nabla R_k(x_k^t), x^t - x \rangle \geq \frac{1}{K} \sum_{k=1}^{K} (R_k(x_k^t) - R_k(x)) - 2\gamma_t G^2
\]

\[
\geq R(x^t) - R(x) - 4\gamma_t G^2,
\]

Let \( \bar{x} \in \mathbb{R}^N \) be such that

\[
\liminf_{t \to \infty} (C(x^t) - C(x)) - 8\gamma G^2 - 2\epsilon \geq C(\bar{x})
\]

(26)

and let \( t_0 \) be large enough so that for all \( t \geq t_0 \), we have

\[
\left| C(x^t) - \liminf_{t \to \infty} C(x^t) \right| \leq \epsilon.
\]

(27)

By combining (26) and (27), we obtain that for all \( t \geq t_0 \)

\[
C(x^t) - C(\bar{x}) \geq 8\gamma G^2 + \epsilon.
\]

(28)

Then from Proposition 1, for all \( t \geq t_0 \),

\[
\|x^t - \bar{x}\|_{\ell_2}^2 \leq \|x^t - x\|_{\ell_2}^2 - 2\gamma (C(x^t) - C(\bar{x})) + 16\gamma^2 G^2
\]

\[
\leq \|x^t - \bar{x}\|_{\ell_2}^2 - 2\gamma G^2.
\]

(29)

By iterating the inequality over \( t \), we have for all \( t \geq t_0 \),

\[
\|x^t - \bar{x}\|_{\ell_2}^2 \leq \|x^0 - \bar{x}\|_{\ell_2}^2 - 2(t - t_0)\gamma G, \]

which cannot hold for arbitrarily large \( t \). This completes the proof.
